We examine the potential of Bayesian optimization for the slow extraction tuning process. In particular, two scenarios are focused on: single energy extraction below the third-order resonance and multiple-energy extraction. At the Xi'an Proton Application Facility synchrotron, low energy slow extraction is adversely affected by the strong space charge effect. The horizontal tune is set below the third order resonance to avoid the large tune shift influence. However, changing the sign of the tune distance flips the slow extraction separatrix distribution in phase space, reducing the extraction efficiency. A high extraction efficiency setting was obtained by parameters scanning in conjunction with operator's experience, but this process is time-consuming. We describe the implementation of Bayesian optimization and show the results in simulation and a proof of principle experiment. Results demonstrate that Bayesian optimization can speed up the tuning procedure while ensuring high quality of the resulting solution. Furthermore, the application of this method in multiple-energy extraction is described and validated only by simulation. In the context of multiple-energy extraction, the objective of optimization is not only to improve the extraction efficiency of an energy step but also to control the area of the stable phase region. To address this multi-objective optimization challenge, the concept of extraction intensity overshoot is used as a proxy for the area of the stable region, while the extraction bump orbit position and angle are incorporated into the optimization parameters. By condensing the two objectives into a single figure of merit, the optimization objective can be reached with Bayesian optimization.

Keywords: Bayesian optimization, Synchrotron, Slow extraction, Beam commissioning

## I. INTRODUCTION

2 Synchrotrons utilizing third-order resonance slow extraction techniques have a wide range of applications,  
3 including in the fields of nuclear physics [1–3], radiation therapy [4–8] and space radiation environment simulation [9–11]. In order to achieve the slow extraction of particles, a number of components are required  
4 to perform a variety of functions. These functions include control of the tune, resonance excitation and creation of extraction bump orbit. Currently, the theory  
5 guiding the design of slow extraction system is well-established [5, 12]. By measuring and correcting relevant extraction parameters to approach the designed  
6 values, a relatively high extraction efficiency can often  
7 be achieved.

8 However, beam dynamics are influenced by numerous non-linearly correlated parameters and are subject  
9 to some physical phenomena. In some specific cases,  
10 the third-order resonance slow-extraction tuning also  
11 counters some problems that increase the time required  
12 for tuning. For example, low-energy proton beams are

22 more affected by space-charge effect due to their low energy. A strong space charge effect can result in a substantial incoherent tune shift [13]. To address such influence on the slow extraction tuning of a 10 MeV proton beam, Y. Yang [14] employed a strategy of positioning the horizontal tune below the third-order resonance. The typical extraction horizontal tune value is about 1.661, which is less than 5/3. The change in tune brings a phase-space flipping that makes some original extraction parameters design experience above 5/3 no longer valid.

32 At XiPAF, experiments have been conducted to improve the efficiency of the extraction process at 10 MeV by Y. Yang, and the extraction efficiency was optimized to exceed 65%. However, the manual optimization of the extraction efficiency is a time-consuming process. In this context, manual optimization refers to the parameters scanning in conjunction with operator's experience.

39 The technique of Multiple-energy extraction (MEE) technique was originally developed and demonstrated at the Heavy Ion Medical Accelerator in Chiba (HIMAC), uses incremental beam deceleration to deliver multiple discrete energies within a single accelerator cycle [15, 16].

44 At HIMAC, the number of energy steps is 202 and the range interval is 1-2 mm water-equivalent length [17]. To increase the extraction efficiency, it is reported that some parameters such as the quadrupole magnet current and the bump orbit have to be adjusted [18]. In Yamagata University, the number of energy steps in-

\* Supported by National Natural Science Foundation of China (No. 12075131)

† Corresponding author, zhengsx@tsinghua.edu.cn

creases to 600 for 0.5 mm water-equivalent length step in order to eliminate the range shifter[19]. Nevertheless, the extraction efficiencies from 600 energy steps are approximately 20 to 70 percent, indicating a potential for improvement[20]. Accordingly, a future objective is to optimize the tune with the aim of enhancing the extraction efficiency[20]. Therefore, optimizing extraction parameters for hundreds of discrete energies in medical synchrotrons within a limited time-frame also presents considerable difficulties.

Additionally, accelerators are susceptible to both short-term and long-term drifts, necessitating regular parameter adjustments to ensure optimal performance. Therefore, a fast beam tuning optimization method is to be expected.

The use of model-independent optimizers has been demonstrated to be an effective approach for automating the tuning process. This is evidenced by the successful implementation of such methods as the simplex algorithm [21–23], extremum seeking [24–26], and robust conjugate direction search [27, 28]. Nevertheless, these methods frequently necessitate a considerable number of costly evaluations and can get stuck in local optima.

Recently, Bayesian optimization (BO), a class of algorithms, has gained prominence in the accelerator field. It is noteworthy that BO has been successfully applied at facilities such as the Linac Coherent Light Source (LCLS) [29, 30] and SwissFEL [31] for tuning free-electron lasers, thereby encouraging its application for other accelerator tuning tasks [32–34]. A comprehensive review of BO applications in accelerator physics can be found in Ref. [35].

Bayesian optimization (BO) is an iterative, model-based algorithm that excels in the efficient optimization of noisy and costly black-box functions [36–38]. This efficiency is achieved through the application of Bayes' theorem, which incorporates prior knowledge and information from previous steps to maximize the value of each new measurement. BO has been demonstrated to outperform other methods [39].

The process of slow beam extraction can be considered a black-box function optimization problem, which makes BO a suitable method for the extraction tuning process. Xi'an Proton Application Facility (XiPAF) synchrotron is a 10~200 MeV proton ring of 30.9 m circumference and it serves as a testbed for this study. In this article, we present the application of BO in two scenarios of the slow extraction process. Firstly, we examine the application of BO to the single energy slow extraction (SEE) below the resonance with simulations and a proof-of-principle experiment. Due to time constraints, only two runs were tested in the experiment. Secondly, we investigate the application of BO to MEE in simulation. In contrast to SEE, the objective of MEE is to enhance the overall efficiency across all energy steps. A detailed account of MEE can be found in Sec. IV. The two cases demonstrate the applicability and efficacy of BO in achieving fast and robust slow extraction optimization.

## II. BAYESIAN OPTIMIZATION AND THE APPLICATION BACKGROUND

### A. Bayesian optimization

In general, BO consists of three main steps, as illustrated in Algorithm 1 [38]. Firstly, BO employs a statistical surrogate model of the objective function,  $f$ . This is typically constructed using a Gaussian process (GP) [40]. This approach is based on the assumption that the objective function,  $f$ , is drawn from a prior probability distribution,  $p(A)$ . Following the initialization and observation of  $f(\mathbf{x})$ , the posterior distribution,  $p[A|f(\mathbf{x})]$ , is constructed in accordance with Bayes' theorem.

$$p[A|f(\mathbf{x})] \propto p[f(\mathbf{x})|A]p(A). \quad (1)$$

The second step is to define an acquisition function  $\alpha(\mathbf{x})$  based on the GP model, which defines the next point to be evaluated. The final step solves for the point (or set of points) that maximizes the acquisition function and thus is predicted to provide the most value towards the optimization objectives. This process is repeated until an optimization criterion is met or a specified number of evaluations is reached.

---

#### Algorithm 1 Bayesian Optimization Process

---

- 1: Specify the prior distribution for the GP.
- 2: Collect initial observations of the objective function  $f$  at  $n_0$  starting points to form the initial dataset  $D_0$ .
- 3: for  $t = 1, 2, \dots$  do
- 4:   Update the GP model using the accumulated data  $D_{t-1}$ .
- 5:   Determine the next evaluation point  $\mathbf{x}_t = \arg \max_a \alpha(\mathbf{x}|D_{t-1})$ .
- 6:   Observe  $y_t$  at point  $\mathbf{x}_t$ .
- 7:   Expand the dataset  $D_t = D_{t-1} \cup (\mathbf{x}_t, y_t)$ .
- 8: end for

### 1. Gaussian process

A GP model is a distribution of possible functions

$$f(\mathbf{x}) \sim \text{GP} [\mu(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')] \quad (2)$$

where  $\mu(\mathbf{x})$  is referred to as the prior mean function and  $k(\mathbf{x}, \mathbf{x}')$  is commonly referred to as the covariance kernel function. To simplify calculations, the prior mean function is given as  $\mu(\mathbf{x}) = 0$ , which is commonly used when the shape of the objective function is unknown.

The covariance function  $k(\mathbf{x}, \mathbf{x}')$ , also known as the kernel, describes the similarity between data points. In this study, we use the Matérn kernel [41, 42] and it is defined as:

$$k_{MA}(\mathbf{x}, \mathbf{x}') = \frac{2^{1-\nu}}{\Gamma(\nu)} \left( \sqrt{2\nu} d/l \right)^\nu K_\nu \left( \sqrt{2\nu} d/l \right). \quad (3)$$

142 Where  $d = \|\mathbf{x} - \mathbf{x}'\|$  is the Euclidean distance between the inputs,  $\Gamma$  is the gamma function, and  $K_\nu$  is the modified Bessel function of the second kind. The length scale of the kernel is denoted by  $l$ , and  $\nu$  controls the smoothness of the resulting function. The Matérn kernel with  $\nu = 2.5$  is often used as a starting point for modeling physical functions in the absence of prior information [35].

150 To emulate the noise present in the real observed signal, a Gaussian distributed noise is added to the covariance function as diagonal terms. Thus, the kernel becomes

$$154 \quad k(\mathbf{x}, \mathbf{x}') = \sigma^2 k_{MA}(\mathbf{x}, \mathbf{x}') + \sigma_{noise}^2 I. \quad (4)$$

155 The covariance function amplitude  $\sigma^2$ , the noise variance  $\sigma_{noise}^2$ , and the length scale  $l$  are referred to as the hyper-parameters, that determine the behavior of the GP.

156 The noise variance  $\sigma_{noise}^2$  is added to the diagonal of the kernel matrix during fitting. This can prevent a potential numerical problem during fitting, by ensuring that the calculated values form a positive definite matrix. It can also be interpreted as the variance of additional Gaussian measurement noise on the training observations. Therefore, the noise level can be determined by measuring the fluctuation of the objective function.

157 Since there is no dedicated optimization data stored in the database, the length scale  $l$  and the covariance function amplitude  $\sigma^2$  are learned from training data collected during optimization. A common strategy for learning the hyper-parameters from experimental data is maximizing the marginal log-likelihood (MLL) of the GP model with respect to the hyperparameter values.

158 In this study, we use the Matérn kernel with its parameter  $\nu$  set to 2.5. Other hyper-parameters are determined as explained above. The GP model building and regression is realized by the Scikit-learn library [43].

## 178 2. Acquisition function

179 With a GP model that infers the posterior distribution of the objective function, an acquisition function  $\alpha(\mathbf{x})$  is constructed to guide the search for the optimum. Maximizing the acquisition function is used to select the next point at which to evaluate the function. That is, we want to sample  $f$  at  $\text{argmax}_x \alpha(\mathbf{x}|D)$ .

180 We use two different acquisition functions in this study: the upper confidence bound (UCB) and the expected improvement (EI). The UCB acquisition function [44] is constructed from the GP prediction mean and standard deviation

$$190 \quad \alpha_{UCB}(\mathbf{x}) = \mu(\mathbf{x}) + \kappa\sigma(\mathbf{x}), \quad (5)$$

191 where  $\mu(\mathbf{x})$  and  $\sigma(\mathbf{x})$  are the GP posterior mean and standard deviation, the parameter  $\kappa$  controls the

193 exploration-exploitation trade-off. Defining UCB with a larger  $\kappa$  value favors exploration, while smaller values of  $\kappa$  prioritize exploitation.

195 The EI acquisition function calculates the expected value of the improvement of a proposed point  $\mathbf{x}$  over the best observed value  $f_{best}$  [45]

$$196 \quad \alpha_{EI}(\mathbf{x}) = \mathbb{E}[\max(f(\mathbf{x}) - (f_{best} + \xi), 0)] \\ 197 \quad = (\mu(\mathbf{x}) - (f_{best} + \xi))\Phi(Z) + \sigma(\mathbf{x})\phi(Z) \quad (6) \\ 198 \quad Z = (\mu(\mathbf{x}) - (f_{best} + \xi))/\sigma(\mathbf{x}),$$

200 where  $\Phi$  and  $\phi$  denote the Cumulative Density Function (CDF) and Probability Density Function (PDF) of a normal distribution. The exploration-exploitation trade-off in EI is determined by a positive parameter  $\xi$ . In general, higher values of  $\xi$  lead to more exploration.

202 205 The BO package implemented in this study is based on an open source constrained global optimization tool [46]. Scipy [47] functionalities are used to maximize the acquisition functions.

## 209 B. Application background

210 211 XiPAF is the first facility in China dedicated to simulate the space radiation environment [10, 48, 49]. It 212 is consisted of a 7 MeV linac injector and a compact 213 synchrotron. The XiPAF synchrotron is a 10~200 MeV 214 proton ring of 30.9 m circumference. The layout of the 215 XiPAF synchrotron is shown in Fig. 1.

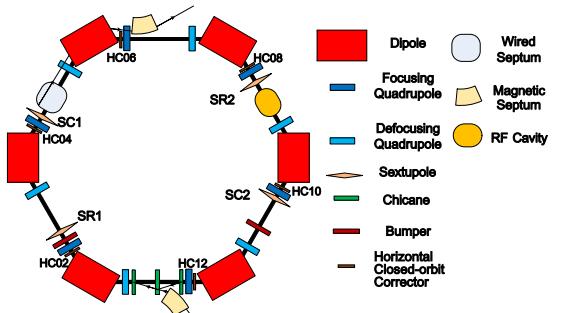

Fig. 1. Scheme of the XiPAF synchrotron layout.

216 217 During irradiation, the beam is slowly and continuously extracted by third-order resonance slow extraction. 218 This is achieved by setting the horizontal tune close to 219 the third-order resonance which for XiPAF is 5/3 and 220 turning on the resonant sextupole magnets (SR). Then 221 a stable triangular phase space area, known as the 'stable 222 region' is formed, separating the stable and unstable 223 betatron motion [5]. With a so called 'radio frequency 224 knockout' (RFKO) system, a transverse radio frequency 225 (RF) field, matched to the horizontal tune, is used to 226 stimulate the transverse movement, while the stable region 227 remains constant [12]. For example, if a parti-

228 cle's revolution frequency is 3.3 MHz and its horizontal  
 229 tune is 1.680, than we need to use a transverse RF field  
 230 with a frequency of 5.544 ( $3.3 \times 1.68$ ) MHz to stimulate  
 231 the transverse movement. Stored particles are gradually  
 232 excited with the transverse emittance growth to leave  
 233 the stable region along the separatrix and extracted by  
 234 the electrostatic wired septum (ES) and magnetic septa  
 235 (MS).

236 The XiPAF synchrotron uses a pair of sextupoles  
 237 (SR1/SR2) for resonance excitation and another pair of  
 238 sextupoles (SC1/SC2) for chromaticity correction. SR1  
 239 and SR2 are placed symmetrically in the ring. SC1 and  
 240 SC2 are also placed symmetrically in the ring. The phase  
 241 advance between SR1 and SR2 is about  $5\pi/3$ , and they  
 242 have the same strength but opposite sign, resulting in  
 243 the same effect on resonance with almost no effect on  
 244 chromaticity. The phase advance between SC1 and SC2  
 245 is also about  $5\pi/3$ , and they have the same strength  
 246 and sign, resulting in the same effect on chromaticity  
 247 with almost no effect on resonance. At XiPAF, the four  
 248 sextupole magnets are powered by four different power  
 249 supplies.

250 The XiPAF slow extraction system is designed with-  
 251 out extraction bump orbit and therefore lacks dedicated  
 252 extraction bump magnets. The ES inner electrode is sit-  
 253 uated 22 mm from the centre of the tube and can be  
 254 adjusted by  $\pm 15$  mm. In most cases, minor adjustments  
 255 to the bending magnet (BM) strength or the position of  
 256 the ES inner electrode are sufficient for the extraction  
 257 tuning.

258 Fig. 2 shows the typical beam current and spill in-  
 259 tensity signals corresponding to the 10 MeV accelera-  
 260 tion and extraction process. The blue curve is the beam  
 261 current in the ring measured by the DC current trans-  
 262 former (DCCT) and the red curve is the spill intensity  
 263 measured by the ion chamber (IC) installed in the high-  
 264 energy beam transport line (HEBT). At 300 ms, the ac-  
 265 celeration phase ends and the beam current is  $\approx 10$  mA  
 266 corresponding to  $\approx 4.4 \times 10^{10}$  protons stored after ac-  
 267 celeration. Between 300 ms and 330 ms, the strengths  
 268 of the sextupole magnets (SR1 and SR2) are ramped up  
 269 to their design values. In this process, a portion of par-  
 270 ticles are extracted in advance because their emittance  
 271 exceeds the area of the stable region. These particles  
 272 are extracted in a non-RFKO extraction process and are  
 273 uncontrollable, which are regarded as beam loss. The  
 274 RFKO system is turned on at 400 ms and ends at 1400  
 275 ms, and the RFKO extraction process is indicated by the  
 276 grey area in Fig. 2.

277 To facilitate the following explanations, some variables  
 278 are defined. We define the number of particles reduced  
 279 in the ring from the start of SR1/SR2 ramping to the end  
 280 of extraction as  $N_{total}$ , corresponding to 300~1400 ms in  
 Fig. 2. We define the number of particles reduced in the  
 ring during the RFKO extraction process as  $N_{rfko}$ , cor-  
 responding to 400~1400 ms in Fig. 2. Finally, the num-  
 ber of particles extracted to the IC during the RFKO  
 extraction process is defined as  $n_{rfko}$ . Based on the vari-

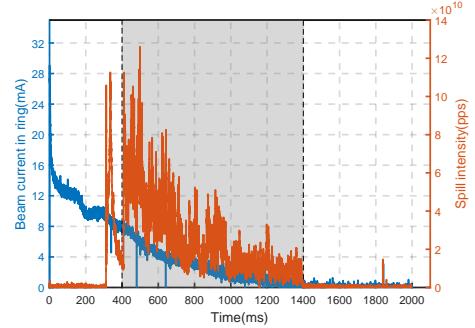

Fig. 2. Typical beam current and spill intensity signals. The blue curve is the beam current in the ring measured by the DCCT and the red curve is the spill intensity measured by the IC installed in the HEBT.

ables defined above, in this study we define two types of  
 extraction efficiencies: the total extraction efficiency  $\eta_{ex}$   
 and the RFKO extraction efficiency  $\eta_{ex,rfko}$

$$\eta_{ex} = \frac{n_{rfko}}{N_{total}}$$

$$\eta_{ex,rfko} = \frac{n_{rfko}}{N_{rfko}}. \quad (7)$$

For the two scenarios discussed in this paper, the common goal is the optimization of efficiency. An increase in total extraction efficiency  $\eta_{ex}$  implies an improvement in RFKO extraction efficiency and a reduction in beam loss for non-RFKO process. Thus, for SEE, the total extraction efficiency can be a suitable optimization target. For MEE, the beam loss during non-RFKO process is represented by another variable called the intensity overshoot ratio. A detailed explanation be can be found in Sec. IV. Intensity overshoot ratio together with the  $\eta_{ex,rfko}$  are used for the optimization in MEE.

### III. IMPLEMENTATION AT LOW ENERGY SLOW EXTRACTION

#### A. Low energy extraction at XiAPF

Originally, the XiPAF synchrotron was designed to extract protons in the energy range 60 to 230 MeV. Protons below this energy are typically produced with the addition of an energy degrader. To avoid this, it is planned to extend third-order resonance slow extraction to perform in the range 10~60 MeV.

Space charge effect causes the incoherent and coherent tune shift of the beam and an incoherent tune spread when the beam traverse distribution is not uniform [13]. For  $9 \times 10^{10}$  protons at 10 MeV, the maximum incoherent tune shift  $\delta Q_{inc} \approx -0.06$ , whilst the tune distance  $\Delta Q_{dis} = Q_x - Q_{x,res} = 1.6816 - \frac{5}{3} \approx 0.0149$ . A typical tune-diagram with  $9 \times 10^{10}$  protons at 10 MeV with a horizontal bare tune of 1.6816 is shown in Fig. 3. The tune distances of some particles approach zero, and they will

319 be preliminarily extracted during the SR1/SR2 ramping  
 320 process. Furthermore, as the extraction progresses, the  
 321 number of particles decreases and the space charge ef-  
 322 fect weakens. The tunes of the remaining particles will  
 323 gradually come back above the  $\frac{5}{3}$  resonance line. At this  
 324 process, some particles would be extracted due to cross-  
 325 ing the resonance line rather than by RFKO. These is-  
 326 sues finally lead to a low total extraction efficiency with  
 327 bare tune  $Q_x > \frac{5}{3}$ . It is therefore proposed that slow  
 328 extraction be performed with  $Q_x < \frac{5}{3}$ .

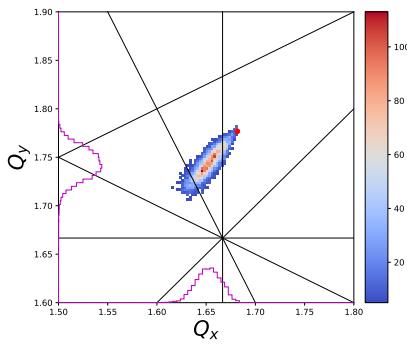

Fig. 3. A typical tune-diagram with  $9 \times 10^{10}$  protons at 10 MeV with a horizontal bare tune of 1.6816.

329 However, for the 10 MeV energy extraction with  $Q_x <$   
 330  $\frac{5}{3}$ , the signs of SR1, SR2, SC1 and SC2 have to be  
 331 changed from  $[-, +, -, -]$  to  $[+, -, -, +]$  to improve the  
 332 extraction efficiency [14, 50, 51]. This is because that  
 333 changing the sign of the tune distance  $\Delta Q_{dis}$  flips the  
 334 slow extraction separatrix distribution in phase space.  
 335 Then, the originally designed  $45^\circ$  angle of the extrac-  
 336 tion separatrix is no longer optimal, and a suitable angle  
 337 is assumed to be between 0 and  $30^\circ$ . To illustrate, the  
 338 schematic of the separatrix distribution flipping in nor-  
 339 malized phase space is shown in Fig. 4. As illustrated  
 340 in Fig. 4(c), after flipping, a particle with a 1.5% mo-  
 341 mentum deviation first enters ES with  $P_x < 0$  and will  
 342 be lost in ES. Furthermore, as illustrated in Fig. 4(d),  
 343 after flipping, particles are susceptible to be lost at MS  
 344 due to the aperture constraints. They are lost before en-  
 345 tering ES, which reduces the extraction efficiency. The  
 346 above phenomena don't occur when the tune distance  
 347  $\Delta Q_{dis} > 0$ .

348 Modifying the positions of the sextupole magnets on  
 349 the ring can alter the angle, but this is evidently more  
 350 laborious and less convenient for extraction tuning. At  
 351 XiPAF, the four sextupole magnets have different power  
 352 supplies. Therefore, we choose to change the signs and  
 353 optimize the strengths. Thus, the roles of SR and SC are  
 354 no longer independent and more time was spent on scan-  
 355 ning the four sextupole strengths. This is the main rea-  
 356 son for the increase of beam commissioning time. Apart  
 357 from the sextupole strengths, the operators have to ad-  
 358 just other parameters such as the tune, the closed orbit  
 359 at the entrance of the ES, the strengths of the ES and

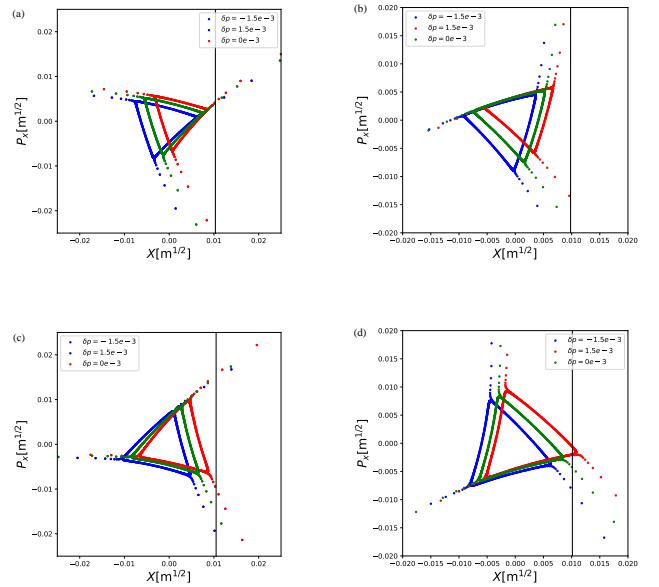

Fig. 4. A schematic of the separatrix distribution flipping in normalized phase space. (a) separatrix distribution at ES entrance with  $\Delta Q_{dis} > 0$ . (b) separatrix distribution at MS entrance with  $\Delta Q_{dis} > 0$ . (c) separatrix distribution at ES entrance with  $\Delta Q_{dis} < 0$ . (d) separatrix distribution at MS entrance with  $\Delta Q_{dis} < 0$

360 MS and so on.

361 Therefore, the beam extraction tuning at the 10 MeV  
 362 energy took several days, while one day is sufficient for  
 363 the normal commission of the extraction of a new energy  
 364 above 60 MeV. The total extraction efficiency at 10 MeV  
 365 was optimized to exceed 65% with  $4.5 \sim 6.5 \times 10^{10}$  pro-  
 366 tons stored before extraction by setting the horizontal  
 367 tune below the third-order resonance (5/3) and using a  
 368 high multiple-frequency RFKO signal [14, 50].

369 What's more, under low energy extraction conditions,  
 370 due to the influence of the space charge effect, the opti-  
 371 mal parameters tend to be strongly correlated with the  
 372 beam intensity before extraction. Consequently, if there  
 373 is a significant change in the beam intensity on any given  
 374 day, the optimal parameters shift accordingly, requiring  
 375 additional time for fine tuning the extraction.

376 We selected seven tuning parameters for the BO based  
 377 on their influence on the extraction process and the prior  
 378 knowledge of experienced operators. The parameters  
 379 are the strengths of 4 sextupole magnets, the focus-  
 380 ing quadrupole (QF) magnet strength, the defocusing  
 381 quadrupole (QD) magnet strength and the BM strength.  
 382 The strengths of 4 sextupole magnets determine the size  
 383 of the stable region, the spiral step and the angle of the  
 384 separatrix in phase space. The strengths of the QF and  
 385 QD magnets mainly determine the horizontal tune which  
 386 subsequently affects the size of the stable region and the  
 387 spiral step. In this section, the optimization goal for SEE  
 388 is to maximize the total extraction efficiency  $\eta_{ex}$ .

389

## B. Optimization results in simulation

390 Before deploying the algorithm in the accelerator, BO  
 391 is first tested by simulation. The primary objective of  
 392 the simulation is to verify the feasibility of BO applied  
 393 to the extraction tuning below the resonance, i.e., to ob-  
 394 tain an extraction efficiency comparable to manual opti-  
 395 mization result within a limited number of evaluations.  
 396 In the simulation, a manually optimized value of 81%  
 397 for the total extraction efficiency was obtained for the  
 398 case of extraction below the resonance[51]. A secondary  
 399 objective is to compare BO with other algorithms.

400 The extraction process is simulated by Syntrack [50],  
 401 which was developed based on Li-track [52] with more  
 402 functions and better usability. The simulation consists  
 403 of 35,000 turns, with the first 5,000 turns corresponding  
 404 to the sextupole magnet ramping up, and the subsequent  
 405 30,000 turns corresponding to the RFKO extraction pro-  
 406 cess. The number of macro-particles in the simulation is  
 407 10000. Based on the particle loss positions at the ring  
 408 and the number of turns, the values of  $n_{rfko}$ ,  $N_{total}$  and  
 409  $\eta_{ex}$  can be obtained from the simulation. Space charge  
 410 force is not considered in the simulation due to time  
 411 constraints. Therefore, the influence of tune spread and  
 412 shift caused by space charge force won't be reflected in  
 413 the simulation. The optimal parameters setting in the  
 414 simulation will also differ from the experiment.

415 The BO algorithm is tested using seven tuning pa-  
 416 rameters as illustrated in Sec. III A. Seven parameters  
 417 have been set with specific bounds. Within these lim-  
 418 its, the range of variation for the horizontal tune is from  
 419 1.6590 to 1.6648. The average closed orbit shift caused  
 420 by changes in bending magnet strength ranges from -1.3  
 421 to 1.3 mm. The strength range for each of the sextupole  
 422 magnets is from 0 to  $12.5 \text{ m}^{-3}$ . Within the simula-  
 423 tion, the boundaries are MIN-MAX normalized in the  
 424 algorithm.

425 Before showing the results of BO, we first give the  
 426 results of 500 evaluations with the random uniform sam-  
 427 pling method, as shown in Fig 5. As illustrated Fig 5,  
 428 only 7 evaluations have a total efficiency greater than  
 85%. Therefore, it can be known that finding a param-  
 430 eters setting with high extraction efficiency within the  
 431 ranges listed above is not a high probability event with  
 432 parameters sampled randomly.

433 In the simulation with BO, the UCB and EI acquisi-  
 434 tion functions are used and the parameter  $\kappa$  for UCB is  
 435 set to 2.5 and  $\xi$  for EI is set to 0.01. The results of the  
 436 seven-dimensional problem using two different acquisi-  
 437 tion functions are shown in Fig. 6.

438 Fig. 6 shows the optimization results over 10 optimiza-  
 439 tion runs using UCB and EI acquisition functions. Each  
 440 run starts from a detuned setting. The settings and the  
 441 random seeds among ten runs are different. The total ex-  
 442 traction efficiencies at the detuned settings are less than  
 443 10%.

444 It is observed that the average efficiency demonst-  
 445 a not increasing trend following approximately 20~30

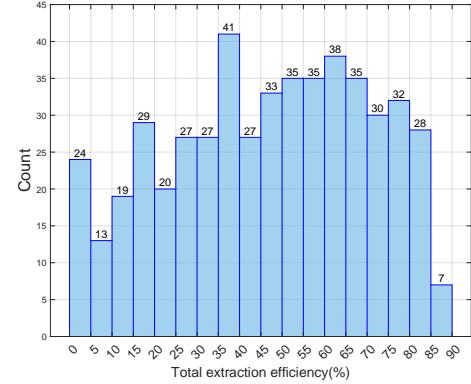

Fig. 5. Results of 500 evaluations with the random uniform sampling method

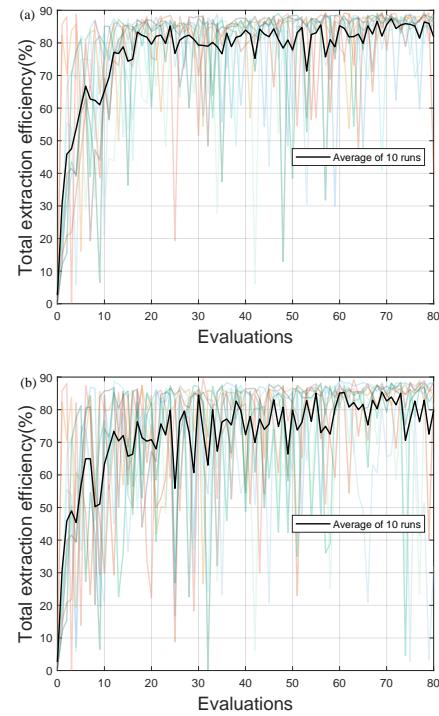

Fig. 6. Optimization results of the total extraction efficiency using EI and UCB acquisition functions for the seven-dimensional problem. (a) shows the results with EI and (b) shows the results with UCB. The black line is the average total extraction efficiency over ten runs. The lines with other colours depict the results of ten runs with different detuned settings.

446 evaluations. For each optimization run in Fig. 6, a pa-  
 447 rameters setting with a total extraction efficiency greater  
 448 than 85% can be found within 32 evaluations. The max-  
 449 imum total efficiency in all 20 runs within 80 evaluations  
 450 is 89.7%.

451 In addition, the results of multiple runs show signifi-  
 452 cant fluctuations, which may be due to the large param-  
 453 eter space in a seven-dimensional problem, where the  
 454 algorithm tends to explore more. When a better point

455 is probed, the algorithm does not ‘exploit’, but contin- 496 this evaluation to show the associated extraction param-  
 456 ues to explore the next perceived better point. When 497 eters. We present the extraction arms corresponding to  
 457 the next point is not optimal, there is a sudden drop in 498 different momentum deviations in the normalized phase  
 458 extraction efficiency, so the whole process exhibits oscil- 499 space, the beam phase space plot at ES, and the enve-  
 459 latory results. The fluctuation of results can be reduced 500 lope changes during the last three turns before entering  
 460 by introducing safety constraints. 501 ES, as shown in Fig. 8.

461 For comparison, we have conducted the same op-  
 462 timization process using the Nelder-Mead algorithm  
 463 (NM) [21], which is a widely used numerical optimization  
 464 technique in the accelerator community and considered  
 465 as a standard benchmark [23]. This method meticulously  
 466 monitors  $d + 1$  ( $d$  refers to the dimension of the param-  
 467 eter space) evaluation points and constructs a simplex  
 468 based on these data points. The Nelder-Mead algorithm  
 469 efficiently finds the optimal solution via geometric mod-  
 470 ifications of the stored simplex, and has been proven to  
 471 converge at a relatively rapid rate. The results of this  
 472 algorithm are shown in Fig. 7.

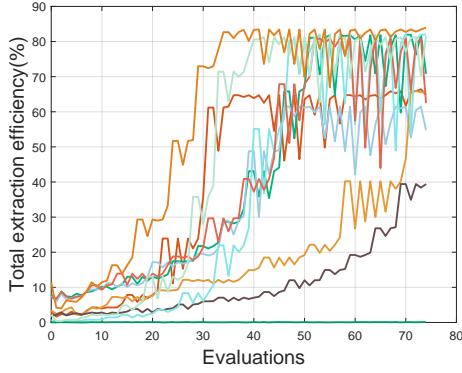

Fig. 7. Optimization results using NM for the seven-dimensional problem. The lines depict the results of ten runs with different colours.

473 In Fig. 7, each run starts from a detuned setting and  
 474 the settings among ten runs are different. The 10 de-  
 475 tuned settings are same with the runs used in Fig. 6  
 476 for comparison. The convergence rate of the Nelder-  
 477 Mead algorithm depends significantly on the choice of  
 478 initial step parameters. In terms of convergence rate, the  
 479 fastest case requires about 30 evaluations, and in some  
 480 cases there is no obvious convergence trend after 75 eval-  
 481 uations. From the convergence results, the extraction  
 482 efficiency can be optimized to 84%. However, in certain  
 483 cases they end up at local optima with extraction effi-  
 484 ciency no greater than 70%, and in some cases, even less.  
 485 Therefore, in order to prevent Nelder-Mead from break-  
 486 ing down and force exploration of the parameter space,  
 487 it is usually designed to be automatically restarted when  
 488 the step becomes too small.

489 From the above results and discussion, it can be con-  
 490 cluded that BO is more effective than NM for the seven-  
 491 dimensional problem, as it achieves a high-efficiency pa-  
 492 rameters setting with a faster rate.

493 In a particular run with the UCB acquisition function,  
 494 the extraction efficiency reached 89% after 31 evalua-  
 495 tions. We select the seven parameters corresponding to

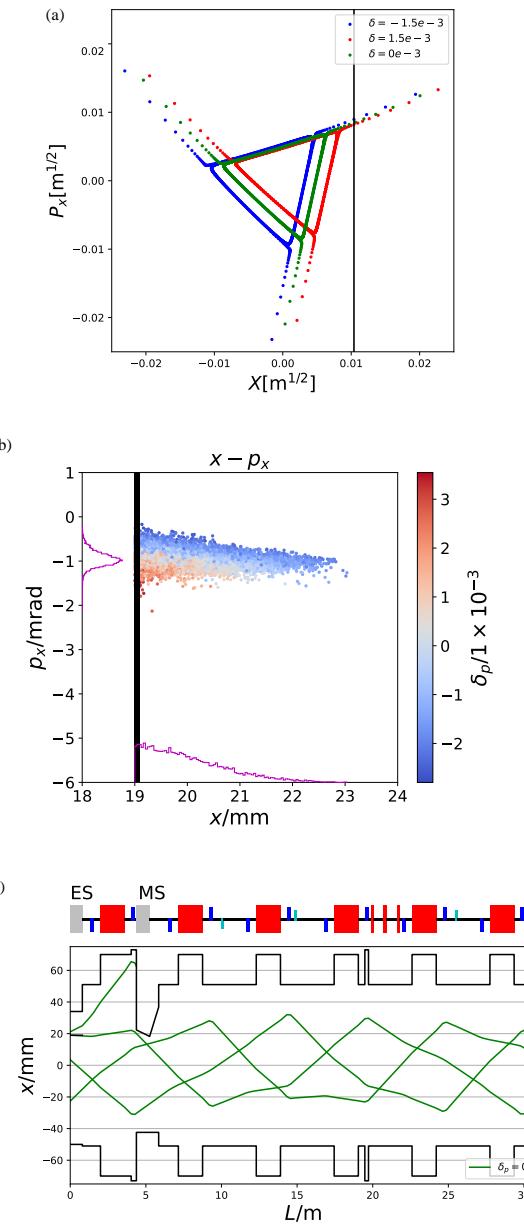

Fig. 8. With an optimal parameters setting, (a) is the schematic diagram of the extraction arms corresponding to different momentum deviations in the normalized phase space, (b) is the phase space plot at ES, and (c) shows the envelope changes during the last three turns before entering ES.

In Fig. 8(a), the extraction arms for particles with momentum deviations of  $\pm 1.5\%$  and 0 are shown in the normalized phase space, which basically coincide. The

difference between the  $P_x$  at the ES inner electrode for particles with momentum deviation of  $-1.5\%$  and  $1.5\%$  is only about  $0.5 \times 10^{-3} \text{ m}^{\frac{1}{2}}$ , which translates to a radian of  $0.41 \text{ mrad}$ . This means a small beam angular spread at ES and the extraction efficiency improved.

Fig. 8(b) is the phase space plot at ES and shows a multi-particles simulation result obtained using Syntrack. The angular spread and spiral step information at ES can be observed. At  $x = 19 \text{ mm}$ , the angular spread is about  $1 \text{ mrad}$  and the spiral step is about  $2 \text{ mm}$ . In the simulation, the tilt angle of ES is set to  $-1.25 \text{ mrad}$ . Consequently, the mean value of  $p_x$  is optimized to approach  $-1.25 \text{ mrad}$ , thereby minimizing the probability of particle loss in ES.

Fig. 8(c) shows the envelope changes during the last three turns for particles with zero momentum deviation. When the momentum deviation is small, the envelope does not exceed the aperture limit within the ring, indicating that the beam loss is primarily due to the larger momentum dispersion at lower energies.

### C. Experimental optimization results

In this section, we describe the results of the BO algorithm implemented at the XiPAF synchrotron low energy extraction tuning. Due to the lack of noise and space-charge effects in the simulation, the main objective of the experiment is to perform the BO algorithm to optimize extraction on the actual machine to confirm the simulation results.

Due to time constraints, the program was not implemented within the accelerator control system. Therefore, in the experiment, all seven parameters were manually adjusted in the control system and the extraction efficiency was also manually updated to the algorithm. The parameters manually adjusted will increase the time and cost of one evaluation. It is important to note that this does not detract from the significance of applying BO. The advantage of BO is that it reduces the number of evaluations compared to other algorithms. It is therefore reasonable to expect the application of BO with parameters automatically adjusted and updated in the future. This will greatly speed up the tuning procedure.

In the experiment, the change in magnetic field strength is achieved by adjusting the gain ( $g$ ) of the magnet current curve. The manually optimized current curve gains  $g_{SR1}$ ,  $g_{SR2}$ ,  $g_{SC1}$ ,  $g_{SC2}$ ,  $g_{BM}$ ,  $g_{QF}$  and  $g_{QD}$  are shown in Tab. 1. As the requirement for extraction with  $Q_x < \frac{5}{3}$  was not considered in the initial design phase of the power supply, the SC power supplies are insufficient to provide the current required. Therefore, the values of  $g_{SC1}$  and  $g_{SC2}$  are set to 1 in Tab. 1.

With the parameters in Tab. 1, the average closed orbit of 6 beam position monitors (BPM) is about  $-0.4 \text{ mm}$ , the horizontal bare tune is about  $1.6606$  and the total extraction efficiency defined above is  $58.9\%$ . With the same parameters setting, the total extraction effi-

cency has reached more than  $65\%$  by Y. Yang.  $58.9\%$  is less than  $65\%$ , indicating that the optimal parameters have drifted.

TABLE 1. Manually optimized current curve gains

Gain	Value	Gain	Value
$g_{SR1}$	0.1	$g_{SR2}$	0.1
$g_{SC1}$	1	$g_{SC2}$	1
$g_{QF}$	0.904	$g_{QD}$	0.9
$g_{BM}$	0.9		

In this experiment we have set the optimization bounds for the current curve gains. For SR and SC, the current curve gain bounds are set to  $[0, 1]$ ; for BM, the gain bound is set to  $[0.8964, 0.9036]$ , with the upper and lower bounds values corresponding to approximately  $\pm 1.2 \text{ mm}$  closed orbit variations; for QD, the gain bound is set to  $[0.891, 0.909]$ ; for QF, the gain bound is set to  $[0.895, 0.913]$ . The current curve gain adjustment ranges for QF and QD correspond to approximately  $\pm 0.006$  horizontal bare tune adjustment ranges. Within the experiment, the boundaries are not MIN-MAX normalized in the algorithm.

The UCB and EI acquisition functions are used and the parameter  $\kappa$  for UCB is set to 2.5 and  $\xi$  for EI is set to 0.01. The optimization run with BO was performed for a fixed number of evaluation steps: 50 steps. This corresponds to about 2~3 hours for each optimization run, where most of the time was spent on manually setting the parameter values and evaluating the extraction efficiency. The computation time of the GP model and the acquisition function is negligible, and due to the machine time constraints, only two runs with UCB and EI acquisition functions were tested. So, this experiment is more of a proof-of-principle experiment: to verify that BO based on Gaussian process modelling is feasible for the black-box function optimization problem of slow extraction efficiency below the resonance with strong space charge effect.

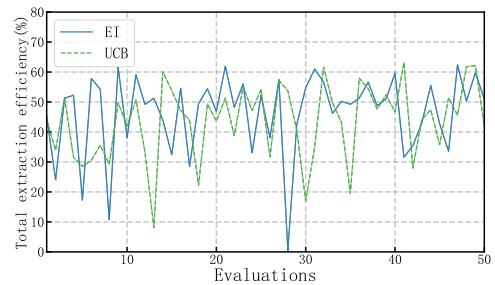

Fig. 9. Experimental optimization results of the total extraction efficiency using BO with two different acquisition function. UCB (green, dashed) and EI (blue, solid) have similar results and are both able to optimize the extraction efficiency within a reasonable number of evaluations.

Fig. 9 shows the results of the experimental optimiza-

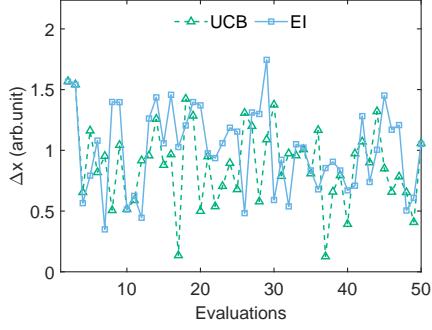

Fig. 10. Behaviour of BO with UCB (green, dashed, triangle) and EI (blue, solid, square) acquisition functions on the seven-dimensional problem. The distance  $\Delta x$  between two successive sampled points is shown in the Min-Max scaled parameter space.

tion. The parameters of the first step are randomly assigned and the same random seed is used for the UCB and EI evaluations. Both EI and UCB acquisition functions are able to find a parameters setting with  $\eta_{ex} > 60\%$  within 50 evaluation steps.

We have also observed and made preliminary analyses of some other phenomena. Firstly, there is no clear upward trend in the early evaluations, which may be due to the relatively high extraction efficiency of the first step and the fast optimization speed. Secondly, the performance of both UCB and EI also presents oscillatory, non-convergent results, which could be attributed to more exploration in the large parameter space. This phenomenon also appears in the simulation with a large parameter space.

The distances  $\Delta x$  between two successive sampled points of BO for the seven-dimensional problem is shown in Fig. 10. It can be seen that BO with UCB and EI acquisition functions show significant fluctuations, reflecting that BO generally samples at a larger distance and does not become trapped in local optima. The evolution of seven current curve gains during the evaluations is shown in Fig. 11. It can also be seen that the current curve gains fluctuate during optimization, especially for  $g_{BM}$ ,  $g_{QF}$  and  $g_{QD}$ .

In this experiment, we validated the feasibility of applying BO to the slow extraction efficiency optimization. For the relatively extreme scenario of low-energy slow extraction, BO is also applicable.

#### IV. IMPLEMENTATION FOR MULTIPLE-ENERGY EXTRACTION

The schematic diagram of MEE is shown in Fig. 12(a). The ability to deliver several energy steps per accelerator cycle reduces the time spent on the reaccelerating the beam during patient treatment and improves the treatment efficiency [53].

In MEE, after the extraction of the initial energy step,

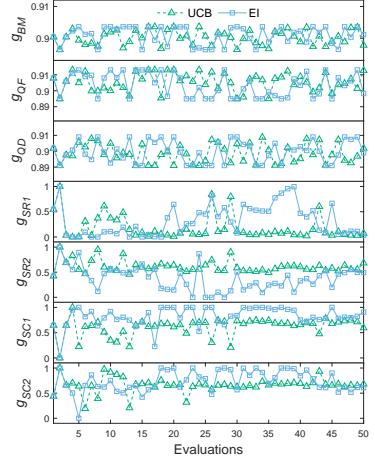

Fig. 11. The evolution of the input parameters is shown over the evaluations including two runs using BO with UCB (green, dashed, triangle) and EI (blue, solid, square) acquisition functions.

the synchrotron decelerates remaining particles to the next lower energy step. An intensity overshoot causing uncontrollable spilled beams will be induced by the emittance growth due to the deceleration. Fig. 12(b) illustrates the process of overshoot formation with the radial distribution function of particles in normalized phase-space ( $X, X'$ ). The blue solid line represents the radial distribution at time  $t_0$ , which corresponds to the end of the  $E_1$  energy step as shown in Fig. 12(a). The blue dashed line represents the radial distribution at time  $t_1$ , which corresponds to the start of the  $E_2$  energy step as shown in Fig. 12(b).  $r_1$  and  $r_2$  represent the boundary of the stable region for  $E_1$  and  $E_2$  respectively.

From  $t_0$  to  $t_1$ , the beam is decelerated and the transverse emittance increases, causing the radial distribution of the beam to change from the blue solid line to the blue dashed line. To illustrate, let us consider the horizontal geometric RMS emittance at  $t_0$  and  $t_1$  to be  $\varepsilon_{x,1}$  and  $\varepsilon_{x,2}$  respectively. It is assumed that the normalized emittance remains constant during the deceleration, therefore, it can be concluded that  $\varepsilon_{x,2} = \varepsilon_{x,1} \frac{p_1}{p_2}$ , where  $p_1$  and  $p_2$  represent the corresponding momentum of  $E_1$  and  $E_2$ . Deceleration means  $p_2 < p_1$ , so  $\varepsilon_{x,2} > \varepsilon_{x,1}$ . Therefore, during the sextupole magnets ramping up at the  $E_2$  energy step, particles whose  $r > r_2$  are prematurely extracted, forming a spill intensity overshoot. The number of particles reduced during this process is defined as  $N_{os}$ .

It is essential to prevent this overshoot, as a significant overshoot in beam intensity can lead to the formation of a dose hot-spot within the target volume [17]. Therefore, a fast beam chopper system has been installed in the high-energy beam transport line (HEBT) at HIMAC to prevent uncontrollable spilled beams from being delivered to the irradiation port [17]. The overshoot and other uncontrollable beam are removed and blocked in the beam dump by the chopper system, more impor-

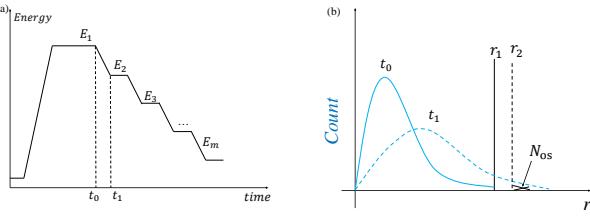

Fig. 12. Schematic diagrams used to illustrate the processes related with MEE. (a) shows the energy variation within a single accelerator cycle. (b) shows the transverse radial distribution variation before and after the deceleration and it also illustrates the process of intensity overshoot formation.

666 tantly, such beam loss should be reduced.

667 The spill intensity overshoot can be reduced by adjust-  
668 ing the size of the stable region area. From Fig. 12, it  
669 is evident that the larger \$r\_2/r\_1\$ is, the fewer the number  
670 of overshoot particles \$N\_{os}\$. In this method, each energy  
671 step \$E\_i\$ has its corresponding stable region area \$A\_i\$, and  
672 it is designed such that

$$673 \quad \frac{A_i}{A_{i-1}} = P_i > 1, (i \geq 2). \quad (8)$$

674 This method has been used by HIMAC to reduce the  
675 intensity overshoot and \$P\_i\$ or \$A\_i\$ is pre designed as a fixed  
676 value [18]. With this method, a high overall efficiency  
677 across all energy steps can be achieved.

678 It is anticipated that the application of BO to MEE  
679 will facilitate and speed up the extraction tuning pro-  
680 cess. In this section, we demonstrate through simula-  
681 tions that it is possible to improve the RFKO extraction  
682 efficiency while controlling the stable region area within  
683 a limited number of evaluations. Although experimen-  
684 tal conditions are not currently available at XiPAF, our  
685 validation work will provide other organizations with a  
686 reference for the selection of relevant algorithms when  
687 tuning MEE.

#### 688 A. Optimization parameters and the objective function

689 One of the main factors affecting the extraction effi-  
690 ciency is the spiral step. The equation of spiral step \$\Delta R\$  
691 is shown as follow

$$692 \quad \Delta R = \epsilon X'_1 + \frac{3}{4} S \{ \sin(3\Delta\mu) (X_1^2 - X'_1^2) + 2\cos(3\Delta\mu) X_1 X'_1 \}. \quad (9)$$

693 where \$\epsilon = 6\pi(Q\_x - Q\_{x,res})\$, \$S\$ is the normalized strength  
694 of the virtual resonance excitation sextupole, \$\Delta\mu\$ is the  
695 phase advance from the resonance excitation sextupole  
696 to the ES and \$(X\_1, X'\_1) = (X\_{ES} - X\_{co}, X'\_{ES} - X'\_{co})\$.  
697 \$(X\_{ES}, X'\_{ES})\$ is the intersection coordinate of separatrix  
698 and the ES inner electrode coordinate in the normalized

699 phase space. \$(X\_{co}, X'\_{co})\$ is the coordinate of the closed  
700 orbit at ES entrance in the normalized phase space.

701 From Eq. (9), the spiral step depends mainly on the  
702 extraction bump orbit, the horizontal tune and the reso-  
703 nance sextupole strength. The area of the stable region  
704 is determined by the horizontal tune and the resonance  
705 sextupole strength. Therefore, when there is a extra need  
706 for enhanced control of the stable region area, the posi-  
707 tion of the extraction bump orbit and its angle can be  
708 considered as new parameters to be optimized in order  
709 to achieve superior optimization outcomes.

710 In this section, the optimization is also carried out  
711 based on XiPAF. XiPAF is not equipped with a group  
712 of extraction bump magnets. Therefore, the extraction  
713 bump orbit is formed by the horizontal closed-orbit cor-  
714 rection magnets. So except for QF, QD, SR, SC strength,  
715 the extraction bump orbit position \$x\_{co}\$ and the angle \$x'\_{co}\$  
716 at ES are two new parameters to be optimized in this  
717 section.

718 The following is a brief explanation of how to deter-  
719 mine the strengths of the horizontal correction magnets  
720 required for the extraction bump orbit at ES. The po-  
721 sitions of the six horizontal correction magnets: HC02,  
722 HC04, HC06, HC08, HC10 and HC12 can be seen in  
723 Fig. 1. There are also six beam position monitors  
724 (BPM02~12) installed at the ring, which are located at

725 the same positions as the corresponding horizontal cor-  
726 rection magnets. To uniquely determine the strengths  
727 of HC02~12, six independent constraints are needed.  
728 With the constraints on the orbit position and angle at  
729 ES already in place, four additional constraints are re-  
730 quired. Closed orbits at BPM02, 08, 10, and 12 are set  
731 to zero as the remaining four constraints. As for an ex-  
732 ample, where the \$x\_{co} = 6\$ mm and \$x'\_{co} = 0\$ mrad, a set  
733 of HC02~12 strengths required can be matched, and the  
734 corresponding ring's closed orbit is shown in Fig. 13.

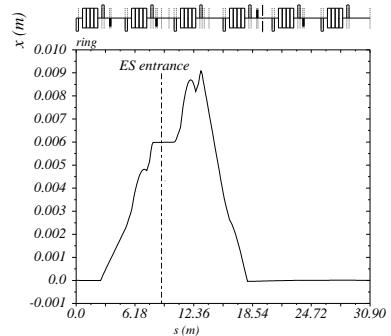

Fig. 13. Schematic diagram of the ring's overall closed orbit variation. The closed orbit position and angle at ES is 6 mm and 0 mrad.

735 \$N\_{os}\$ reflects the absolute size of the intensity over-  
736 shoot. However, our interest also extends to the relative  
737 size of the intensity overshoot. Therefore, we define a  
738 variable called the intensity overshoot ratio \$\eta\_{os}\$ to facil-

739 itate the subsequent discussion. It is defined as

$$740 \quad \eta_{os} = \frac{N_{os}}{N_{rm}}, \quad (10)$$

741 where  $N_{rm}$  refers to the number of particles that re-  
742 main in the ring prior to the implementation of sextupole  
743 ramping.

744 Now we turn to the design of the objective function.

745 Unlike the optimization objective in the Sec. III, this sec-  
746 tion deals with a multi-objective optimization problem.  
747 Besides aiming for a high RFKO extraction efficiency,

748 we also want the area of the stable region to be as close  
749 as possible to a target value. Considering that the area  
750 of the stable region is not an easily measurable physical  
751 quantity, we choose to use the overshoot ratio  $\eta_{os}$  as a  
752 proxy for the area of the stable region. From Fig. 12(b),  
753 it is known that as long as the beam distribution re-  
754 mains unchanged before the sextupole magnets ramping  
755 up,  $\eta_{os}$  and the stable region area can be considered as a  
756 one-to-one correspondence. From another point of view,  
757 the demand for area control in practical applications is  
758 essentially a demand for controlling the overshoot ra-  
759 tio. And it is practical to use the overshoot ratio as an

760 optimization objective without spending extra time to  
761 measure the horizontal tune to compute the area of the  
762 stable region.

763 Given the definitions and explanations above, the op-  
764 timization objectives are clear:  $\eta_{ex,rfko}$  should be as high  
765 as possible, and  $\eta_{os}$  should be as close as possible to the  
766 target overshoot ratio  $\eta_{os,t}$ , i.e.,

$$767 \quad \begin{aligned} & \max \eta_{ex,rfko}, \\ & \min |\eta_{os} - \eta_{os,t}|. \end{aligned} \quad (11)$$

768 For such a multi-objective optimization problem, we  
769 attempt to condense the two objectives into a single fig-  
770 ure of merit, thus converting it into a single-objective  
771 optimization problem. Though in multi-objective opti-  
772 mization, the true goal is to find the Pareto front (PF).  
773 For the sake of convenience, we choose the aforemen-  
774 tioned approach since we consider that the two objectives  
775 do not exhibit strong competition by introducing the ex-  
776 traction bump orbit position and angle as parameters to  
777 be optimized.

778 We propose the following form of the objective func-  
779 tion

$$780 \quad f(\eta_{ex,rfko}, \eta_{os}) = \begin{cases} \eta_{ex,rfko} e^{-\frac{|\eta_{os} - \eta_{os,t}|}{\omega}}, e^{-\frac{|\eta_{os} - \eta_{os,t}|}{\omega}} > k \\ \eta_{ex,rfko} k, e^{-\frac{|\eta_{os} - \eta_{os,t}|}{\omega}} \leq k \end{cases}, \quad (12)$$

781 where  $k$  and  $\omega$  are hyper-parameters that need to be set  
782 based on the specific situation. The exponential term  
783 reflects the penalty effect on the RFKO extraction ef-  
784 ficiency. The hyper-parameter  $\omega$  determines the rate  
785 of decay of the exponential term. The piecewise design  
786 is considered because, during the actual optimization,  
787 there have been instances where a large overshoot ra-  
788 tio causes the exponential decay term to approach zero,  
789 making the figure of merit insensitive to variations in  
790 RFKO extraction efficiency. So, when the exponential  
791 term is smaller than  $k$ , the RFKO extraction efficiency  
792 is only penalized by a fixed value of  $k$ .

793 **B. Optimization results in simulation**  
794 In this section, we will verify the feasibility of applying  
795 BO to such a multi-objective extraction process through  
796 simulation. Since XiPAF currently lacks the experimen-  
797 tal conditions, we artificially introduce a certain amount  
798 of output noise, to demonstrate the efficacy of BO with  
799 observation noise. For the hadron therapy, the required  
800 proton energy range is approximately 60~230 MeV. Fur-  
801 thermore, the influence of the space charge effect on slow  
802 extraction can be disregarded. Consequently, the condi-  
803 tions and process of the simulation are similar to those  
804 described in Sec. III B, with the exception that the ex-  
805 traction simulation is conducted with  $Q_x > \frac{5}{3}$  and a  
806 proton energy of 60 MeV.  
807 As an example, consider the beam tuning for an en-  
808 ergy step in MEE. It is assumed that the designed stable  
809 region area  $A_0$  for this step is  $21.7 \pi \text{ mm} \cdot \text{mrad}$ . In the  
810 event of an unoptimal parameters setting with a horizon-  
811 tal tune of 1.6800 and an area of  $A_0$  with no extraction  
812 bump orbit at ES, the RFKO extraction efficiency is 86%  
813 and the overshoot ratio is 6.88% in the simulation. We  
814 aim to find a set of better extraction parameters that  
815 maximize the RFKO extraction efficiency while keeping  
816 the stable region area or the overshoot ratio of 6.88%  
817 unchanged.

818 After determining the specific optimization objectives,  
819 we first identify the specific parameters to be optimized

820 and their ranges. For the extraction above the third-  
821 order resonance, the strengths of SR1 and SR2 are iden-  
822 tical and their signs are fixed as  $[-, +]$ . The strengths of  
823 SC1 and SC2 are also identical but their signs are fixed as  
824  $[-, -]$ . Therefore, only two absolute strength values of the  
825 SR and SC are selected as the optimization parameters.  
826 Including the QF strength, QD strength, ES closed-orbit  
827 position and angle, there are a total of six parameters  
828 to be optimized in the simulation. Each of these six  
829 parameters has a defined bound. Within the bounds,

the horizontal tune can vary between 1.6741 and 1.6817, the stable region area can vary approximately between 6.5~32.1  $\pi mm \cdot mrad$ , and the horizontal chromaticity can vary between -0.21 and -0.76. The closed-orbit position at ES entrance  $x_{co}$  ranges from 0 to 6 mm, and the closed-orbit angle  $x'_{co}$  ranges from -1.5 to 1.5 mrad. Within the simulation, the boundaries are MIN-MAX normalized in the algorithm.

Having determined the specific parameters to be optimized, we now discuss the determination of the hyperparameters in Eq. 12. We know that  $\eta_{os,t}$  is 6.88%. We preliminarily choose  $\omega = 0.13$ , which is approximately twice  $\eta_{os,t}$ . Additionally,  $k$  is preliminarily taken as 0.2, corresponding to a breakpoint  $\eta_{os} = 0.28$ . An overshoot ratio of 28% is already quite large, so we do not consider the exponential term from approaching zero under large  $\eta_{os}$ . Then, a specific objective function is shown as follow.

$$f(\eta_{ex,rfko}, \eta_{os}) = \begin{cases} \eta_{ex,rfko} e^{-\frac{|\eta_{os}-0.0688|}{0.13}}, & e^{-\frac{|\eta_{os}-0.0688|}{0.13}} > 0.2 \\ 0.2\eta_{ex,rfko}, & e^{-\frac{|\eta_{os}-0.0688|}{0.13}} \leq 0.2 \end{cases} \quad (13)$$

Next, we discuss the impact of noise. Between the two parameters: RFKO extraction efficiency and overshoot ratio, the fluctuation in RFKO extraction efficiency is often small, on the order of 1%, while the fluctuation in the overshoot ratio is typically larger. The main reason for the larger fluctuation in the overshoot ratio is the poor reproducibility of the beam distribution over different machine cycles. Based on historical data, the standard deviation of the overshoot ratio fluctuation can reach up to 10%. Therefore, to take into account the effect of the overshoot ratio fluctuation, the  $\eta_{os}$  is calculated using the formula below

$$\eta_{os} = \eta_{os,ori} + \eta_{err}, \eta_{err} \sim N(0, 0.1\eta_{os,t}), \quad (14)$$

where  $\eta_{os,ori}$  refers to the original overshoot ratio, as obtained from the Syntrack simulation and  $\eta_{err}$  is a normally distributed random variable with mean zero and standard deviation of 0.1 times  $\eta_{os,t}$ . With considering the impact of noise, the  $\sigma_{noise}$  parameter in the Gaussian process has also been appropriately adjusted.

In this optimization process, the UCB and EI acquisition functions are used, with the parameter  $\kappa$  for UCB set to 2.5 and  $\xi$  for EI set to 0.01. The optimization results are shown in Fig. 14.

As illustrated in Fig. 14, the average objective function over ten runs demonstrates a not increasing trend following approximately 20~30 evaluations. For each optimization run in Fig. 14, a parameters setting with the objective function greater than 0.9 can be found within 35 evaluations, and greater than 0.94 within 50 evaluations. The maximum total efficiency in all runs is 0.96.

To gain a more intuitive understanding of the optimization outcomes for RFKO extraction efficiency and overshoot ratio, the variations in RFKO extraction efficiency and overshoot ratio with the number of evaluations during a specific run are presented in Fig. 15.

As illustrated in Fig. 15, the extraction efficiency in this run exhibited a potential for optimization exceeding 95%, with an overshoot ratio approximating 0.0688. Based on these observations, it can be postulated that the anticipated optimization objectives have been met

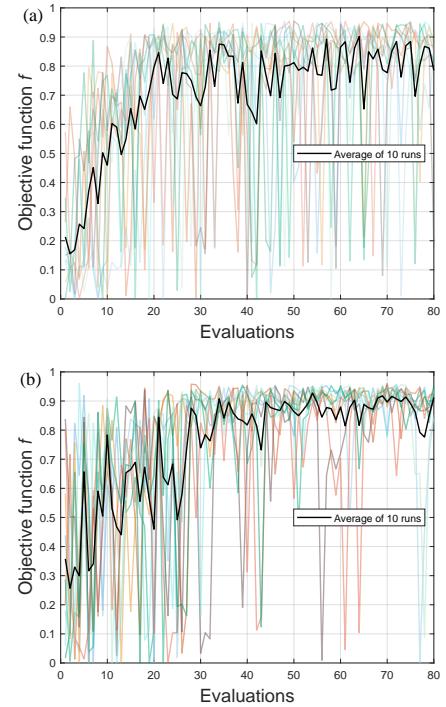

Fig. 14. Optimization results using EI and UCB acquisition functions for the six-dimensional problem. (a) shows the results with EI and (b) shows the results with UCB. The black line is the average result over ten runs. The lines with other colours depict the results of ten runs with random initial settings.

through the application of BO and the designed objective function.

In the optimization runs corresponding to Fig. 15, the variations in the ratio  $g$  of QF, QD, SR, and SC strengths, as well as the variation of  $x_{co}$  and  $x'_{co}$  are shown in Fig. 16.

Taking the parameters from the 48th evaluation in the above EI run as an example. For this evaluation, the horizontal tune is 1.680, RFKO extrac-

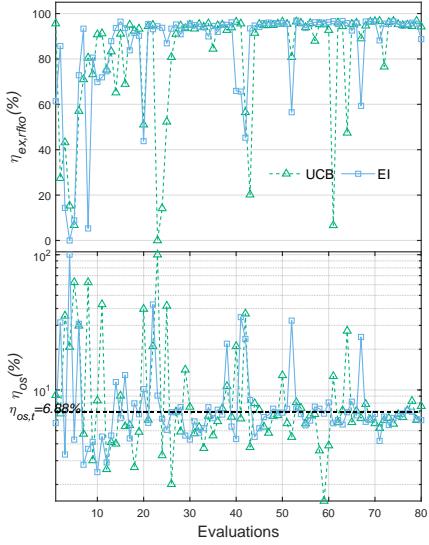

Fig. 15. Variations of RFKO extraction efficiency and overshoot ratio using UCB (green, dashed) and EI (blue, solid) simulation is also meaningful, as it provides a reference acquisition functions for the six-dimensional problem during a specific run.

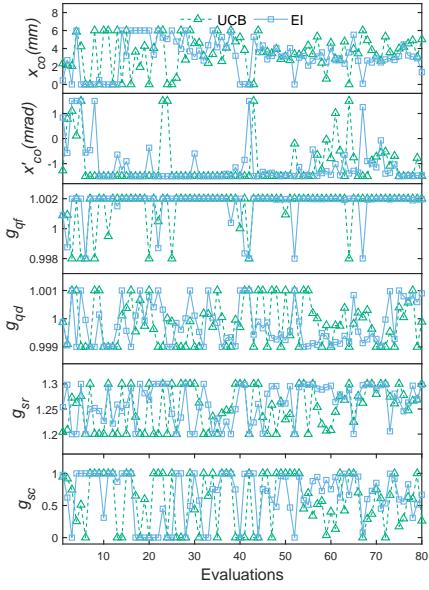

Fig. 16. The evolution of the input parameters is illustrated over the evaluations including two acquisition functions: UCB (green, dashed, triangle) and EI (blue, solid) in simulation is also meaningful, as it provides a reference acquisition functions for the six-dimensional problem during a specific run.

## V. DISCUSSION

We have mentioned that the intensity overshoot is caused by emittance growth due to the deceleration. This can be avoided by re-accelerating from low to high energy, but there are some problems with this option. In hadron therapy, a tumor is typically irradiated from a deep slice to a shallow slice, which means that the required beam energy should change from high to low energy. In addition, due to the space charge effect, the synchrotron can store more particles at high beam energy. For example, the number of particles that XiPAF synchrotron can store at 200 MeV is about twice as many as at 60 MeV. To store more particles, and considering the tradition of hadron therapy, MEE from high to low energy is chosen as the basis for our study.

The relationship between the intensity overshoot ratio  $\eta_{\text{os}}$  and the stable region area  $A$  in simulation is shown in Fig. 18. The horizontal RMS emittance in the simulation is  $3\pi \text{ mm} \cdot \text{mrad}$ . The relationship between  $\eta_{\text{os}}$  and  $A$  is not linear, as shown in the Fig. 18. As  $A$  decreases, the growth rate of  $\eta_{\text{os}}$  increases. This is due to the fact that the transverse radial distribution resembles the Rayleigh distribution, as shown in Fig. 12(b). Therefore, in the actual optimization stage, we need to make  $\eta_{\text{os}}$  larger, so that  $\eta_{\text{os}}$  is more sensitive to the variation of the stable

region area. The  $\eta_{\text{os}}$  caused by the deceleration is around 1% or even less in the experiment. Therefore, in the optimization stage of an energy step, the emittance needs to be intentionally increased before the SR ramping. This can be achieved by pre-excitation with RFKO. It is important to note that this extra pre-excitation process is not required in the actual treatment stage.

In MEE simulation, random noise is introduced to the intensity overshoot. It is acknowledged that a more real-

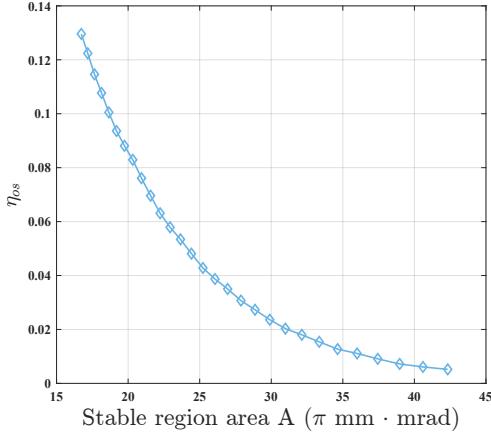

Fig. 18. Schematic of the relationship between the intensity overshoot ratio  $\eta_{os}$  and the stable region area  $A$  in simulation. The horizontal RMS emittance in the simulation is  $3 \pi \text{ mm} \cdot \text{mrad}$ .

945 istic approach would be to add noise equivalent to condi-  
 946 tions seen in the accelerator, and their causes, e.g. power  
 947 converters. However, adding the noise of the actual sit-  
 948 uation involves the specific spectrum and amplitude of  
 949 the ripple, the beam distribution jitter, and other fac-  
 950 tors. The straightforward approach of introducing noise  
 951 to the output is a simple method that is employed in sim-  
 952 ulation to verify the reliability of BO in the context of  
 953 output noise. In the event of a suitable opportunity aris-  
 954 ing, experimental validation of the BO applied to MEE  
 955 is scheduled to take place.

956 Finally, a concise discussion is provided herein on the  
 957 implementation of BO to the accelerator control system.  
 958 The process variables of the control system currently  
 959 contain the magnets' DC values, the outputs of mea-  
 960 surement devices such as the DCCT, BPM and IC, and  
 961 so on. So some simple beam tuning tasks are currently  
 962 automated at XiPAF. For example, the parameters grid  
 963 scanning is applied for the optimization of low-energy  
 964 beam transport line (LEBT) and the synchrotron injec-  
 965 tion process. But current curve gains, extraction effi-  
 966 ciency and the extraction overshoot ratio are not pro-  
 967 cess variables yet. One reason for this is that the power  
 968 supply design does not take into account the control of  
 969 the current curve gains, which can only be set manually.  
 970 Another reason is that the extraction efficiency and the  
 971 overshoot ratio currently rely on manually reading the  
 972 DCCT and IC results and using additional scripts for the  
 973 calculations. So in order to automate the operation of  
 974 BO, the above two problems need to be solved. On the  
 975 one hand it is desired that the current curve gain can be  
 976 automatically controlled as a process variable. Or just

977 set a target value of the current flattop and the power  
 978 supply can automatically generate transition curves be-  
 979 tween different flattops. On the other hand, it is desired  
 980 to integrate the processing scripts for the extraction ef-  
 981 ficiency and overshoot ratio into the control system. Fi-  
 982 nally, with the the BO algorithm relized in the control  
 983 system program, the automatization of BO can be ex-  
 984 pected.

## VI. SUMMARY

985 This article presents the application of Bayesian op-  
 986 timization to the third-order resonance slow extraction  
 987 process. The focus is on two scenarios of slow extraction,  
 988 with the XiPAF synchrotron serving as a testbed.

989 Firstly, the optimization of total extraction efficiency  
 990 for SEE below the third-order resonance was described,  
 991 and the algorithms were tested in simulation and a proof-  
 992 of-principle experiment. Due to time constraints, only  
 993 two runs were tested in the experiment. For the extrac-  
 994 tion below the resonance, the strengths of the four sex-  
 995 tuple magnets need to be individually optimized, which  
 996 increases the beam tuning time. Our findings demon-  
 997 strate that BO is an effective method for optimizing the  
 998 total extraction efficiency for SEE in a limited number  
 999 of evaluations. Additionally, we have shown that BO  
 1000 outperforms the commonly used Nelder-Mead method  
 1001 in simulation.

1002 Secondly, we demonstrated the application of the BO  
 1003 method to maximize the RFKO extraction efficiency  
 1004 while controlling the stable region area in MEE. In or-  
 1005 der to address this multi-objective optimization problem,  
 1006 the intensity overshoot was employed as a proxy for the  
 1007 area of the stable region, and the extraction bump or-  
 1008 bit position and angle were included as optimization pa-  
 1009 rameters. In light of the distinctive nature of the inten-  
 1010 sity overshoot, we delineate the design of the objective  
 1011 function, which condenses the two objectives into a sin-  
 1012 gle figure of merit. To substantiate the efficacy of our  
 1013 approach, we conducted a simulation wherein random  
 1014 noise is introduced to the intensity overshoot. The re-  
 1015 sults demonstrate that BO can rapidly optimize the ob-  
 1016 jective function while yielding the anticipated outcomes.  
 1017 As demonstrated in the example, the RFKO extraction  
 1018 efficiency can be enhanced to above 95% and the inten-  
 1019 sity overshoot ratio closely aligns with the target area  
 1020 value 0.0688.
